ABSTRACT

Aims. Using the CFBDSIR wide field survey for brown dwarfs, we identified CFBDSIRJ214947.2-040308.9, a late T dwarf with atypically red J − Ks colour.

Methods. We obtained an X-Shooter spectra, with signal detectable from 0.8 μm to 2.3 μm, which confirmed a T7 spectral type with an enhanced Ks-band flux indicative of a potentially low-gravity, young, object.

Results. The comparison of our near infrared spectrum with atmosphere models, for solar metallicity, shows that CFBDSIRJ214947.2-040308.9 is probably a 650–750 K, log g=3.75–4.0 substellar object. Using evolution models, this translates into a planetary mass object, with an age in the 20–200 Myr range. An independent Bayesian analysis from proper motion measurements results in a 87% probability that this free-floating planet is a member of the 50–120 Myr old AB Doradus moving group, which strengthens the spectroscopic youth diagnosis.

Conclusions. By combining our atmospheric characterisation with the age and metallicity constraints arising from the probable membership to the AB Doradus moving group, we find that CFBDSIRJ214947.2-040308.9 is probably a 4–7 Jupiter masses free-floating planet with an effective temperature of ~700 K and a log g of ~4.0, typical of the late T-type exoplanets that are targeted by direct imaging. We stress that this object could be used as a benchmark for understanding the physics of the similar T-type exoplanets that will be discovered by the upcoming high contrast imagers.

1. Introduction

The Astronomical Union definition that the planetary mass range is below deuterium-burning mass (13M_Jup; Boss et al. 2003) while brown dwarfs and stars populate the mass range above is challenged by a string of recent discoveries, notably from possible Isolated Planetary Mass Objects (hereafter IPMOs, or equivalently free-floating planets in clusters, see for instance Zapatero Osorio et al. 2002; Burgess et al. 2003; Haisch et al. 2010; Peña Ramírez et al. 2011, 2012), which are more likely formed like stars but reside in the planetary mass range. There are also many cases of field brown dwarfs whose lower mass limit is well within the official planetary mass range (see for instance Knapp et al. 2004; Burgasser et al. 2006; Cruz et al. 2009; Lucas et al. 2010).

Send offprint requests to: P. Delorme, e-mail: Philippe.Delorme@obs.ujf-grenoble.fr. Based on observations obtained with SOFI on the NTT at ESO-La Silla (run 086.C-0652(A)). Based on observations obtained with X-Shooter on VLT-UT2 at ESO-Paranal (run 087.C-0562(A)). Based on observation obtained with WIRCAM at CFHT (programs 09AF21,10BF26 and 11BD86).

http://www.dtm.ciw.edu/boss/definition.html

Burningham et al. 2011b; Liu et al. 2011; Luhman et al. 2011; Cushing et al. 2011; Albert et al. 2011). However, in all these cases there are significant uncertainties on the actual masses of these possible free-floating planets, mostly because of the age/mass/luminosity degeneracy that affects the determination of the physical parameters of substellar objects. This degeneracy can be lifted when the age of the source can be constrained independently, usually through cluster or association membership. There is however no isolated object that combine such an undisputed age constraint with spectroscopic low gravity signatures that would be compatible with a planetary mass. There is nonetheless strong evidence that IPMOs do exist, at least since the discovery of 2M1207B by Chauvin et al. (2004) has established the existence of a ~5M_Jup companion around a ~25M_Jup object that would be almost impossible to form through planetary formation mechanisms. This means stellar formation processes such as cloud fragmentation (see for instance Bate 2009) or disk fragmentation (see for instance Stamatellos et al. 2011), can form planetary mass objects. Peña Ramírez et al. (2012) has recently identified a population of IPMOs in the σ-Orionis cluster, and hinted that they could be about as numerous as deuterium-burning brown-dwarfs. This would indicate that there is a significant population of...
overlooked IPMOs in the solar vicinity, both in the field and in young moving groups and clusters. Another source of IPMOs could be ejected planets (e.g. Veras & Raymond 2012; Mocek & Veras 2012), since massive planets such as HR8799bcde (Marois et al. 2008, 2010), if ejected from their host star, would look like regular field T dwarfs after a few hundred Myr. Another strong evidence that IPMOs exist is the detection of a few free-floating planets by gravitational lensing by Sumi et al. (2011); Strigari et al. (2012), though these objects -or at least a fraction of them- could also be regular planets orbiting at sufficiently large separation from their host star that the latter is not detectable in the lensing event.

The detection of IPMOs can therefore provide constraints on ejection scenarios and on the low-mass end of the stellar mass function, though these constraints will not be independent since it is observationally challenging to imagine a way to discriminate between a 5M_Jup ejected planet and a brown dwarf of the same mass. However, the spectral energy distribution of these isolated objects will provide useful information on the substellar evolution and substellar atmosphere models, especially if their age is known, and regardless of their formation mechanisms. These constraints are especially valuable because the spectral energy distribution of an IPMO is expected to be identical to the spectral energy distribution of planets with similar masses orbiting at large separation -hence with negligible irradiation- from their host stars. In this light, such free-floating planets could serve as benchmarks for the design and operation of the direct imaging surveys for exoplanets, notably with the upcoming new generations planets finder instruments such as SPHERE (Beuzit et al. 2008), GPI (Graham et al. 2007), or HiCIAOH (Hodapp et al. 2008). Young IPMOs of a few Jupiter masses would be interesting analogs of the exoplanets these instruments will be able to detect. Since they are not affected by the glare of a host star, it is comparatively easy to obtain relatively high signal to noise, moderate resolution spectroscopic information so that they can serve as prototypes to understand the physics of massive exoplanets atmospheres.

We present in section 2 the detection of a low-gravity T dwarf, CFBDSIR2149, hereafter CFBDSIR2149, that is probably a 4–7M_Jup free-floating planet. In section 3, we describe our spectroscopic data reduction and present the full Near-InfraRed (NIR) spectrum of this object, highlighting its low gravity features. In section 4 we discuss its likely membership to the young moving group AB Doradus (hereafter ABDMG). In section 5 we analyse its spectrum in the light of the age and metallicity constraints that would be brought by its probable ABDMG membership, and derive its fundamental physical parameters. Finally we discuss some of the implications of this discovery.

2. Photometry of CFBDSIR2149

2.1. Discovery and identification as a late T dwarf with K_s-band excess

The Canada-France Brown Dwarf Survey InfraRed (CFBDSIR; Delorme et al. 2010) is a NIR coverage of the CFHTLS/CFBDS (see Delorme et al. 2008) fields with available deep z′-band images. It covers 335 square degrees with J-band WIRCam (Puget et al. 2004) images. Cool brown dwarfs candidates are identified from their very red z′ − J colour (see Fig. 2) and CFBDSIR2149 was identified as such by the standard CFBDSIR analysis pipeline (see Delorme et al. 2010). After analysing and cross-matching a stack of two 45s-long WIRCams J-band exposure from the CFBDSIR acquired on August 13th and 14th, 2009, with the corresponding CFBDS-RCS2 (Yee et al. 2007; Delorme et al. 2008) 360s z′ exposure, we highlighted CFBDSIR2149 as a z′ dropout with z′ − J > 3.8.

This promising candidate was confirmed by NIR follow-up observation at the ESO-NTT telescope (run 086.C-0655(A)) on 2010, September 24, with a NTT-Sofi (Moorwood et al. 1998) J-band detection (See Fig. 1). This candidate was a very cool brown dwarf and not a transient source like an extragalactic supernovae or an asteroid that could have caused our initial J-band detection and accounted for the z′-band non-detection. The real-time analysis of the NTT J-band data prompted further observations of this cool brown dwarf in H and K_s during the following night. The resulting very blue J − H = −0.5 confirmed it as a very late T dwarf while the neutral to red J − K_s ∼ 0 highlighted it as a peculiar K_s-band flux enhanced late T dwarf (see 2). Note that throughout this work, YJHK/K_s magnitudes are given in the Vega system while z′ mag are in the AB system (Fukugita et al. 1996).

2.2. Near-infrared imaging: reduction and analysis

In addition to this SOFI photometric follow-up, we obtained higher signal to noise photometric data in Y, J and K_s from CFHT Director Discretionary Time, in December 2011, as well as CH_kon imaging acquired in September 2010. This WIRCam data, using the MKO photometric system, is deeper and offers a larger time-base to derive the proper motion of CFBDSIR2149 using the WIRCam August 2009 detection images as a first epoch. Since
WIRCam has a larger field of view than SOFI it also allows to use more stars for an accurate photometric and astrometric calibration.

Both SOFI and WIRCam observations used a standard dithering pattern to allow the construction of a sky frame and were reduced and analysed using the same home-made pipeline. For the WIRCam observations, we used one (out of 4) $10^4 \times 10^4$ chips, on which the target was centred. For each filter, flat fielding and bad pixel removal were carried out using ESO-eclipse software package (Devillard 2001). A sky frame, constructed by median-combining the dithered raw exposures, was subtracted to each exposure. The resulting reduced individual exposures were cross matched using Swarp (Bertin 2006) and combined with Swarp (Bertin 2010), using the inverse of each image background noise as weight. This weighting particularly improved the signal to noise of the WIRCam images which were acquired with a rapidly evolving airmass, while the target was setting. The absolute astrometric and photometric calibrations in $J$, $H$ and $K_s$ were carried out using the 2MASS point source catalog (Cutri et al. 2003) as a reference, with 3 valid references on the SOFI field of view and 15 on the WIRCam chip field of view. For the photometric calibration of $z'$, $Y$ and $CH_{1\text{on}}$ data we used the CFHT-provided zero points and absorption values.

We extracted the photometry and astrometry of CFBSR2149 and of the reference stars by Point Spread Function (PSF) fitting using Sextractor, with a spatially variable PSF model built from each science image using PSFex (Bertin & Arnouts 1996; Bertin 2006; Bertin et al. 2012). The resulting photometry is shown on Table 1. The $H - CH_{1\text{on}}$ of 0.9, tracing the methane absorption bands around 1.6 $\mu$m is typical of a T7.5±0.5 brown dwarf (calibration by L. Albert, private communication), while the red $J - K_s$ and very red $H - K_s$ (see Fig. 2) indicate a weak Collision Induced Absorption of H$_2$ (CIA), resulting in an enhanced $K$-band flux (see Knapp et al. 2004, for instance). The weak CIA would be caused by a lower than usual pressure in the photosphere, either due to low gravity, high metallicity or a combination of both. We caution that such colour diagnosis can be misleading, at least for objects in the L/T transition where cloud coverage effects can blur the conclusions (see the unusual blue and red $J - K$ in the T2.5/T4 binary of Artigau et al. 2011). However the later spectral type of CFBSR2149 (T7) places it in a temperature range where models, and the associated colour diagnosis, are usually more reliable, mainly because most clouds have condensed at such low temperatures. This also make the red $J - K$ association with low gravity/high metallicity more robust for late T dwarfs such as CFBSR2149 than it is for the red, also probably low gravity, L dwarfs identified by Cruz et al. (2003); Allers et al. (2011); Faherty et al. (2012).

2.2.1. WISE data

We searched the WISE (Wright et al. 2010) all-sky release catalog for a mid-infrared counterpart of CFBSR2149. There is no signal related to our target in W3 and W4 channels, but we found a very faint object at its exact position in W2 and slightly offset in W1. The catalog-provided photometry for this counterpart gives W1=17.4±0.47 and W2=15.99±0.37. Though this mid-infrared signal to noise is extremely low, the resulting $H - W2=3.9±0.4$ colour is consistent with CFBSR2149 being a late T dwarf (see Figure 1 of Mainzer et al. 2011).

3. Spectroscopy of CFBSR2149

3.1. Spectroscopic follow-up and reduction

Given the faintness ($J = 19.3$) of CFBSR2149, it was not observed in spectroscopy with Sofi at NTT and was therefore put in the queue of our 087.C-0562 ESO-VLT X-Shooter observations as a very high priority target. It was observed on September, 5 and September 27, 2011, in two ESO observing block (hereafter OB) achieving a total exposure time on target of 5850 s, split in 4 A-B nods on slit of 2×732 s each. We used 0.9" slits for both visible and NIR arms.

The spectra was reduced using the latest ESO X-Shooter pipeline (Modigliani et al. 2010), which produced a 2-dimensions, curvature corrected, spectrum of the NIR arm of X-Shooter from 0.99 to 2.5 $\mu$m and of the visible arm, from 0.6 to 1.02 $\mu$m for each OB. No signal was retrieved for wavelengths shorter than ~0.8 $\mu$m, but a low signal-to-noise ratio (SNR) spectrum of the optical far-red was recovered between 0.8 and 1.0 $\mu$m. The trace was extracted using our own IDL procedures, using Gaussian boxes in the spatial dimension all along the spectral direction. The noise spectrum was obtained by measuring the dispersion along 10 spectral pixels on a noise trace obtained by subtracting the science trace by itself shifted of 1 pixel. Since the shift is much smaller than the full spectral resolution (~4.2 pixels in the NIR and 6.0 in the visible), this effectively removes the science spectrum, but keeps the information on the actual background and photon noise on the science trace.

The two resulting 1-D spectra of each OB were then divided by the spectrum of telluric standard stars observed just after or just before each OB and reduced and extracted using the same pipeline as the science OBs. The two spectra corrected from telluric absorption were then combined through a weighted average using the inverse variance as weight to construct the science spectrum. A noise-weighted average significantly improved the signal-to-noise ratio since the quality of data obtained on September 5th was noticeably better than that obtained on September 27th. Because the resulting spectrum at $R$≈5300 has a low SNR and most of the late T physical parameters exploration is carried out using lower resolution spectra, we made a sliding noise-weighted average on 25, 100 and 200 pixels in the spectral dimension, producing 3 spectra, at a resolution of respectively $R=900, 225$ and 113 in the near-infrared. The visible spectra was similarly binned on 400 pixels, with a corresponding resolution $R=132$. The noise-weighted average in the spectral dimension makes use of the full resolution of X-Shooter to down-weight the narrow wavelength ranges affected by OH telluric emission lines, thus improving the SNR with respect to a regular average or, more importantly, to lower resolution observations.

The same reduction and extraction procedures were used for the NIR and visible arms of X-Shooter, but the SNR in the small common wavelength interval between the 2 arms is low (about 1), which makes difficult to rescale the visible data to the NIR data scale. Since we have no $z'$ detection of CFBSR2149, we cannot calibrate the visible spectrum on photometry. We therefore caution that
Table 1. Photometry of CFBDSIR2149 with NTT and CFHT. The corresponding exposure time is indicated between parentheses.

Fig. 2. Near-IR MKO colours of CFBDSIR2149 (Red square) compared to known field T dwarfs. The arrows in $z' - J$ colours indicates this colour is a lower limit since we have no $z'$-band detection. Open squares are CFBDS T dwarfs [Albert et al. (2011)], the plus signs are 111 dwarfs from [Knapp et al. (2004)], crosses are 73 dwarfs from [Chiu et al. (2006)] while open triangles are late T dwarfs from [Burningham et al. (2008, 2009, 2010); Delorme et al. (2010); Lucas et al. (2010)].

We checked the flux homogeneity of this large wavelength coverage spectral data by calibrating it on our existing WIRCam and NTT photometry (see Table1). We synthetized the uncalibrated science spectrum colours by integrating them on WIRCam global transmission, including filter, instrument and telescope transmission and the detector quantum efficiency (see section 2.2 of [Delorme et al. 2008b, for details) and determined a scaling factor for each of the broadband filter range so that the $YJHKS$ Vega
magnitudes derived for CFBDSIR1458AB spectrum would match those observed in broadband photometry. The resulting calibration factors are summarised in Table 3 showing that photometry and spectrophotometry agree within 1σ.

As shown on Table 3 we also derived spectrophotometric $C_{H\alpha}$ and $C_{H\alpha}^{off}$ magnitudes from the spectra. Since we don’t have a parallax for CFBDSIR2149 yet, we can only derive colours from the spectra. We had to anchor these colours to the $J$-band photometry to obtain the spectrophotometric $C_{H\alpha}$ $C_{H\alpha}^{off}$ magnitudes in the WIRCam photometric system.

We used this X-Shooter spectrum to derive the spectral indices defined in Burgasser et al. (2006); Warren et al. (2007); Delorme et al. (2008a) that trace the strength of several molecular absorption features typical of T dwarfs. As shown on Table 2 the atmospheric features are typical of a T7-T7.5 dwarf, with a significantly enhanced K/J index, telltale of a weak CIA (though greenhouse effect could participate to K-band flux enhancement, see Allard & Homeier (2012), and therefore of a low pressure photosphere (Leggett et al. 2002; Burgasser et al. 2004; Golimowski et al. 2004; Knapp et al. 2004; Burgasser et al. 2006; Hiranaka et al. 2012) propose an alternative explanation for the similarly red spectral energy distribution of some peculiar L dwarfs, which could be caused by a thin dust layer above the photosphere. Since most of the dust is condensed in late T dwarfs photospheres, this alternative hypothesis is much weaker for objects as cool as CFBDSIR2149, making a lower than usual pressure in the atmosphere cooler than 650 K. Conversely, they are too strong in models at a temperature cooler than 650 K.

4. Kinematic analysis: does CFBDSIR2149 belong to the young moving group AB Doradus?

4.1 Proper motion

We used the multi-epoch images described in the previous section to derive the proper motion of CFBDSIR2149. To improve our astrometric accuracy, we did not use the absolute positions of the source measured on each image, but calculated a relative local astrometric solution for each pair of first epoch and second epoch measurements. This was achieved by cross-matching first and second epochs and calculating the astrometric solution (using Scamp Bertin 2006) of the second epoch using the first epoch image as the reference.

The most significant source of error was the centroid positioning error of this faint source, thus we used PSF-fitting with Sextractor to improve our accuracy. Given the very asymmetrical spectral energy distribution of late T dwarfs another source of error is the Atmospheric Chromatic Refraction (ACR, see e.g. Dupuy & Liu (2012)). Since the flux barycenter in broad band filters is not at the same wavelength position for T dwarfs than it is for the background stars we used to derive the astrometric solution, ACR introduces a systematic shift in the centroid position. This depends mostly on the filter used and on the airmass at the time of the observations. This effect is relatively small in the NIR (a few mas. Albert et al 2011), but we caution our error estimates for proper motion measurements do not take this systematic error into account and hence those errors represent lower limits. We also neglect parallax effects, which should be below 10mas, given the photometric distance (35-50pc) and our 28 months baseline between our first (13/08/2009) and our last (23/12/2011) epochs. According to Tinney et al. (2003) the bias from ACR is negligible in J-band, and therefore, both the parallax effect and ACR effects are negligible compared to our measurement accuracy ($\sim 30\text{mas.yr}^{-1}$), meaning the uncertainties are dominated by measurements errors and not by systematics for our J-band data. This proper motion measurement are given in Table 4 together with the least square linear fit of proper motion using as input for each epoch the measurement of the position relative to the first epoch. The fit was weighted at each epoch by the inverse of the error squared. Since we are only interested by the relative motion, we assumed the first epoch measurement error to be infinitesimal and affected the full error of each epoch $\sigma_p = \text{epoch 1 measurement to epoch } n$. The measurements using the other filter sets are much more dispersed, but as shown on Table 4 including all data in the fit decreases the fit measurement error, though the use of different filters should add small ACR systematics. In the following, we use the proper motion derived from the full data set, but caution that the error bar associated is a lower limit. A-contrario, the error we derived on J-band data only, with well controlled systematics and much less data, can be seen as a conservative upper limit of the error bars of the full data set.
Fig. 3. Comparison of CFBDSIR2149 full spectrum at R=225 with BT-Settl models of varying effective temperature (left) and gravity (right). Last row shows the models agreeing best with $J, H, K$ data for field gravity (left, log $g=4.5$ and $T_{\text{eff}}=800$ K) and free-floating planet gravity (right, log $g=3.75$ and $T_{\text{eff}}=650$ K).
Table 2. Value of the NIR spectral indices from Burgasser et al. (2006); Warren et al. (2007); Delorme et al. (2008a) for some of the latest known brown dwarfs. We calculated the values of the other brown dwarfs using spectra from Burgasser et al. (2006); Delorme et al. (2008a); Binningham et al. (2009, 2010).

Fig. 4. Vectors representing the norm and direction of the proper motion of CFBSIR2149 compared to the map of ABDMG members proper motions.

4.2. Young moving group membership probability

Since the photometry and the spectrum of CFBSIR2149 show tentative youth indicators, we have estimated the probabilities that this object is a member of several moving groups and associations (β-Pictoris, Tucana-Horologium, AB Doradus, TW Hydrae [Zuckerman et al. 2004], Columba, Carina, Argus, the Pleiades, ε Chamaeleontis, the Hyades and Ursa Majoris [Torres et al. 2008]), as well as a field member.

To do this, we used a Bayesian inference method which consists in answering to the following question: given the XYZ galactic position and UVW space velocity of our object as well as the distribution of equivalent quantities for each group and the field, what is the probability it is actually a member of each group? The field and groups correspond to the different hypotheses and in principle, the input parameters to such an analysis would be the XYZUVW for our object. However, we do not have a measurement for its radial velocity nor its trigonometric distance. There is a standard way to deal with this which is generally called marginalisation over unknown parameters, consisting of repeating the analysis with several values for this parameter, then comparing the sum of the resulting probability densities for each hypothesis. For more details, we refer the reader to Feigelson & Jogesh Babu (2012) for a general description of Bayesian inference, as well as Malo et al. (submitted) for an analysis similar in many ways to what we do here. We used the same XYZUVW distributions for each group and the field as described in Malo et al. (submitted).

We will highlight the three major differences between this analysis and ours: (1) we took into account the measurement errors on input parameters, by convolving each association’s parameter distribution with a Gaussian of characteristic width corresponding to this error. (2) We treated distance and radial velocity as marginalized parameters, instead of just distance. (3) We took into account what is called the prior probability, which was set to unity in the referred work. The value of this prior corresponds
to the probability our object is a member of a given group if we have absolutely no input data on the object. This is the simple ratio of the number of members to the group in question with the total number of stars we could have observed, reflecting the obvious fact that any random star had a much higher probability to belong to the field than to any young association, since there are many more field stars that there are young associations members. If this quantity is accurately estimated, it would ensure that 90% of members with 90% membership probability would be actual members. Without this prior, CFBDSIR2149 would have a 99.9% membership probability to belong either the AB Doradus moving group (ABDMG) or to the β-Pictoris moving group (BPMG). Notably, the membership probability to ABDMG is very high because of the proximity of CFBDSIR to ABDMG cinematic locus (see Figure 3).

To give a value to this prior for the young associations hypotheses, we used the number of known young moving group members. For the field hypothesis, we used the fact our object is conservatively younger than 500 Myr since its spectrum is rather indicative of an age in the 20 to 200 Myr range. Given that evolutionary and atmosphere models of young substellar objects are not yet fully reliable, we preferred to set a conservative upper age limit of 500 Myr. To inject this information in our Bayesian inference, we simply treated the prior as the ratio of stars in each moving group with the total population of field stars younger than 500 Myr distant from 0 to 100 pc in a galactic disk simulation from Besançon Galaxy model (Robin et al. 2003). We are confident this range of distances is reliable, since the young moving groups we considered lie within 100 pc of the Sun and the photometric distance of our candidate is comfortably below 100 pc. This estimate is in fact quite conservative since it is generally accepted that the populations of young moving groups are still incomplete, meaning we might underestimate their respective membership probabilities. A third reason makes our membership probability conservative: when considering the field hypothesis we don’t use the proper motion distribution of specifically young field objects, but of the general field population. Since young field objects have a narrower proper motion distribution (Robin et al. 2003), we therefore overestimate the field membership probability.

With this Bayesian analysis that conservatively takes into account that young field stars are much more numerous than young association stars, we find CFBDSIR2149 has a membership probability of 79.4% for AB Doradus and 13.3% for the field. The third most likely hypothesis, a membership to the young moving group βPictoris, has a 7.3% probability.

This makes CFBDSIR2149 a good candidate member to the 50-120 Myr old, solar metallicity, ABDMG moving group (Zuckerman et al. 2004, Luhman et al. 2003, Ortega et al. 2007). The most likely values of the marginalized parameters (distance and radial velocity) for the most probable hypotheses (AB Doradus, field, and Beta Pictoris membership) are shown on Figure 3. For the young field hypothesis, the Bayesian estimate provide a statistical (most likely) distance of 31 ± 13 pc and a radial velocity of −6 ± 9 km s⁻¹. According to the Allard et al. (2012) BT-Settl isochrones, the photometric distance of a 700 K, 500 Myr old brown dwarf with CFBDSIR brightness would be between 25 and 40 pc (respectively using the Kₖ and J-band photometry), in reasonable agreement with the Bayesian kinematic estimation. A younger age -our field prior is compatible with any age below 500Myrs- would lead to higher photometric distances and therefore to a more marginal agreement for the field hypothesis.

For the highest probability hypothesis, namely that our target belongs to ABDMG, the statistical distance is 40 ± 4 pc and radial velocity of −10 ± 3 km s⁻¹. According to the Allard et al. (2012) BT-Settl isochrones, the photometric distance of a 700 K, 120 Myr old brown dwarf with CFBDSIR brightness would be between 35 and 50 pc (respectively using the Kₖ and J-band photometry), which is in good agreement with the Bayesian estimation.

For the BPMG hypothesis the Bayesian estimate provide a statistical (most likely) distance of 27 ± 3 pc and a radial velocity of −7 ± 2 km s⁻¹. According to the Allard et al. (2012) BT-Settl isochrones, the photometric distance of a 650 K, 20 Myr old field brown dwarf with CFBDSIR brightness would be between 25 and 35 pc (respectively using the Kₖ and J-band photometry), in reasonable agreement with the Bayesian kinematic estimation.

If we integrate the probability distribution of Figure 5 over the photometric distance estimate range, we can obtain a membership probability that include this information. We use the photometric distance estimate for the field for an age of 500Myr which is the closest to the field Bayesian estimate, and therefore slightly favours the field hypothesis. This yields a membership probability of 87% for the ABDMG, 7% for the BPMG, and 6% for the field. Also, since a fraction of field objects are younger than 150 Myr, the actual probability that CFBDSIR2149 is actually younger than 150 Myr is higher than its membership probability to ABDMG and BPMG. Taking that into account, CFBDSIR2149 has a membership probability of 87% for the ABDMG, 7% for the BPMG, 3% for the young field (age < 150 Myr) and 3% for the field (150 Myr ≤ age ≤ 500 Myr).

We caution that this introduces significant uncertainties into the calculation, because of the low reliability of photometric distance estimates. To dampen this concern, we derive in the following what could be seen as lower limits of ABDMG membership probability by looking at scenarios even more favourable to the field, using a prior allowing objects as old as 1 Gyr and 10 Gyr to be included in the prior. This is very conservative because CFBDSIR2149 spectrum indicate a much younger age (< 200 Myr, see previous section). With the prior including all field stars younger than 1 Gyr, this yields 72% membership probability to ABDMG, 22% to the field of all ages below 1 Gyr, and 6% to the BPMG, based on position and proper motion alone. If we integrate the Bayesian distance estimates on the photometric distance estimate ranges, we derive a membership probability of 83% for the ABDMG, 6% for the BPMG, 3% for the young field (age < 150 Myr) and 8% for the field (150 Myr < age < 1 Gyr). If we use the even more extreme prior including all field stars younger than 10 Gyr and integrate these probabilities on the photometric distance estimates (using a distance range of 20-35 pc for a 5Gyr TT dwarf), we still get 63% membership probability to ABDMG, 32% to the field of all ages below 10 Gyr, and 5% to the BPMG. As discussed in the previous section, the spectral features of this object are not compatible with an old age, unless it has a strongly super-solar metallicity.
5. Physical properties of CFBDSIR2149

5.1. Comparison to other late T dwarfs

A direct comparison of CFBDSIR2149’s spectrum with the spectra of other T7-T8.5 brown dwarfs (see Fig. 8), clearly shows its enhanced K-band flux. The spectrum of CFBDSIR2149 shows another low gravity feature, namely the enhanced absorption by the 1.25 μm potassium doublet (see Fig. 6). According to Allard & Homeier (2012), the strength of the doublet in the spectra depends both on the abundance of potassium in the atmosphere, and on the strength of the CH₄ and H₂O absorptions bands that shape the pseudo-continuum through which the doublet forms. At T dwarf temperatures, a lower gravity increases the doublet strength by playing on each of these parameters: the pseudo-continuum is weakened at low gravity for a given effective temperature while the potassium abundances tend to increase because of enhanced vertical mixing effects in low gravity atmospheres. The same trend has been empirically observed in T dwarf by Knapp et al. (2004).

This doublet decreases in strength from T4 to T7, until it totally disappears on regular field dwarfs later than T7 (Knapp et al. 2004), and should be almost absent of the T7/T7.5 spectrum of CFBDSIR2149 if it had field gravity and solar metallicity. The comparison with the T7 2M0727+1710 (See Fig. 7), which has already been identified as a low gravity T7 by Knapp et al. (2004) illustrates that the KI absorption doublet is more prominent in CFBDSIR2149.

Another interesting object to compare with is the very red T8.5 brown dwarf Ross458C (Scholz 2010; Goldman et al. 2010; Burgasser et al. 2010; Burningham et al. 2011a) which presents a K-band flux excess comparable to what we observe for CFBDSIR2149. As discussed in Burgasser et al. (2010); Burningham et al. (2011a), this object shows many features of low gravity and belongs to a young stellar system (150-800 Myr), with a slightly higher than solar metallicity ([Fe/H]~0.2-0.3).

Before we engage in a closer comparison between CFBDSIR2149 and Ross458C, we have to point out
that since CFBDSIR2149 appears slightly warmer than Ross458C, it should have, because of effective temperature alone, a redder $J - K_s$ (See Fig 2) and a higher J/K spectral index. This makes the direct comparison of these gravity-sensitive features difficult: they are slightly stronger in CFBDSIR2149 but this difference, including the presence of the 1.25 $\mu$m potassium doublet, might be fully accounted for by the difference in effective temperature rather than by an even lower gravity. In order to compare the colours of both objects using the same photometric system, we calculated the NIR colours of Ross458C in the WIRCam filter system using the spectra provided by [Barningham et al. 2011a]. The resulting colours are shown in Table 5 and are very similar to those observed for CFBDSIR2149. Note that the $J - K$ colour of Ross458C with WFCAM filter system is much bluer ($\sim -0.25$, [Barningham et al. 2011b]) because the atypical K-band filter used on WFCAM cuts a significant part of T dwarf flux blueward of 2 $\mu$m and extends red-ward of 2.3 $\mu$m where late T dwarfs have no flux left.

Because of the degeneracy between effects of low gravity and high metallicity, the similar colours and spectral features of CFBDSIR2149 with respect to Ross458C can be explained either by a similar $\log g$/[M/H] combination or by a younger age and a more common solar metallicity for CFBDSIR2149. There is also the possibility that CFBDSIR2149 is older and has an even higher metallicity than Ross458C but this is much less probable both because of its kinematics and because of the scarcity of significantly over-metallic stellar systems (only $\sim 4$% of stars have metallicity $>0.3$, [Santos et al. 2005]).

Given the probable association of CFBDSIR2149 to the 50-120 Myr AB Doradus moving group, the hypothesis that it is a slightly warmer, slightly younger solar metallicity counterpart of Ross458C is most likely, especially because it is also consistent with the $[\text{M}/\text{H}]=0.02 \pm 0.02$ metallicity distribution derived by [Ortega et al. 2007] for ABDMG members. According to the Lyon stellar evolution models [Baraffe et al. 2003], at solar metallicity, such a 650-750 K brown dwarf aged 50 Myr has a mass of 4 to 5 Jupiter masses and a log g of about 3.9. This would make CFBDSIR2149 a "free-floating planet", with the same atmospheric properties as any 50 Myr old, 4-5 $M_{\text{Jup}}$, T-type exoplanet, and therefore an invaluable benchmark for exoplanets atmospheres studies. In the case we would adopt the higher age hypothesis of 120 Myr ([Luhman et al. 2003; Ortega et al. 2007]), the conclusion would be similar, CFBDSIR2149 then being a 120 Myr old, 6-7 $M_{\text{Jup}}$ free-floating planet with a log g of $\sim 4.1$.

5.1.1. Revisiting Ross458C

The young age hypothesis for Ross458C is supported by the fast rotation (11 km s$^{-1}$, [Donati et al. 2008]) observed for its primary M1 star Ross458A. The corresponding upper limit of the period (in case the projected rotational speed $V\sin(i) = V_\text{eq}$, the equatorial rotation speed) of $\sim 2.5$ days. [Delorme et al. 2011] established that early M dwarfs in the Hyades and Praesepe had already converged toward a clean mass-period relation. Gyrochronology [Harris 2003] therefore allows asserting that almost all early M dwarfs which rotate faster than the 12-14 days observed in the early M dwarfs of these $\sim 600$ Myr clusters are younger than the cluster themselves. The exceptions are the few stars which experienced significant angular momentum transfer from orbital momentum to rotational momentum through close tidal interactions within a multiple system. Since Ross458A has a rotation period much shorter than 12-14 days, and is not known as a very close dynamically interacting binary, we can safely deduce that the Ross458 system is younger than 600 Myr. This upper age limit is more stringent than the 800 Myr upper age limit from [Burgasser et al. 2010] and is consistent with the 200-300 Myr derived from the spectral analysis of Ross458C and CFBDSIR2149.

Given the probable higher metallicity and lower temperature of Ross458C, the gravity of both objects should be similar. Because of the fast cooling down of a substellar object during its first few hundreds Myr, a gravity within 0.2 dex. of CFBDSIR2149, for the 650-700 K Ross458C, is only compatible with an age lower than 200 Myr (300 Myr if we use the older age estimate for the AB Doradus moving group), with a corresponding maximum mass of 8 (respectively 10) $M_{\text{Jup}}$. These rough estimates, also compatible with the age value from [Burgasser et al. 2010], would redefine the $T_{\text{eff}}$ of brown dwarf Ross458C as an exoplanet orbiting the Ross458 stellar system, if we follow the controverted International Astronomical Union official definition of a planet, even if its formation mechanisms are likely more akin to the formation of multiple systems. Indeed, the formation of Ross458 through planetary formation scenarios such as core accretion or gravitational instability is unlikely both because of the very large separation (1200 AU, [Scholz 2010]), and low mass of the primary Ross458A.

5.2. Comparison to models

We used several sets of models to match the observed spectra of CFBDSIR2149. The corresponding plots are shown in Fig. 8 (BT-Settl models) and Fig. 9 and include planetary atmosphere models meant for the HR8799 planets [Currie et al. 2011] adapted from [Barrows et al. 2003] (hereafter referred as BSL03) and from [Madhusudhan et al. 2011], ([hereafter referred as MBC2011]) as well as the BT-Settl-models.

We did not attempt a numerical fit of our observed spectra to these various models grids because of the strong (and model dependent) systematics uncertainties in atmosphere models, notably missing CH$_4$ absorption lines blue-ward of 1.6 $\mu$m whose lack is obvious in Fig 9 not included on the $H$-band peak. We preferred matching models visually, rather than injecting ad-hoc restrictions in a fit by artificially weighting out parts of the models we suppose are affected by systematics. Discussing the resulting numerical values of such a fit would not be more relevant than discussing the models that visually match the observed spectrum and would unfairly hide some of the limitations that come with comparing poorly constrained models and poorly sampled model grids to noisy data.

The main difficulty to match CFBDSIR2149 spectrum is to find a model that correctly reproduces both its very deep CH$_4$ absorption in the $H$-band and its strongly enhanced $K$-band flux. The former is easily matched by...
Fig. 7. Comparison of CFBDSIR2149 spectrum (red) in the $J$ band, with low gravity (bottom, Leggett et al. 2002, McLean et al. 2003) and regular (top, Strauss et al. 1999, McLean et al. 2003) T6 (left) and T7 (right) brown dwarfs (black). The dashed line indicate the position of the potassium doublet.

all models with cool (700 K) temperatures and relatively high gravities (log $g = 4.5$-5.0; see Fig. 9) while the latter can be matched by warmer, low gravity models (see Fig. 8), but the combination of both is difficult to reproduce. The MBC models with clouds of type "A", "AE" and "AEE" very significantly fail to reproduce the SED of CFBDSIR2149 (see the “A” case on the lower right panel of Fig. 9), because they predict an extremely red NIR SED, due to their very thick cloud layers. In the "A" case, the cloud model includes no upper cloud boundary at all, i.e. no dust sedimentation effects of any kind, corresponding to the simplified cases of fully cloudy atmospheres like the AMES-Dusty models. The "E" models by comparison implement a steeply decreasing condensate density above a certain pressure level given as a model parameter, and can thus be tuned to produce clouds comparable to the BT-Settl models or the Marley & Saumon models for a certain $f_{\text{sed}}$. As seen on Fig. 9 these "E" cloud models as well as the BSL2003 and BT-Settl models offer a decent match to the spectrum when using relatively cool temperatures (650-700 K) to depress the H-band flux and relatively low gravities (log $g = 3.75$-4.1) to enhance the $K$-band flux, but all models suffer from missing CH$_4$ lines blue-ward of 1.6 $\mu$m. This systematic shortcoming acknowledged, comparison with models gives a temperature of 650-750 K and log $g$ of 3.75 to 4.1 for CFBDSIR2149. BT-Settl models favour a cool 650 K, log $g = 3.75$ value that would be only compatible, according to the Baraffe et al. (2003) substellar evolution models with hypothesis that our target is a member of the 12 Myr-old $\beta$-Pictoris moving group, and with ABDMG membership but only for its youngest age estimate (50 Myr; Zuckerman et al. 2004). Conversely, the ages derived from the MBC2011 "E" cloud models and BSL2003 models (also using Baraffe et al. (2003) models to translate temperature and gravity into age and mass) would be fully compatible with the probable (>95%) hypothesis that CFBDSIR2149 is younger than 150 Myr. Even in the extreme hypothesis that this object would be aged 500 Myr, its mass (11M$_{\text{Jup}}$) would still be below the deuterium burning mass of 13M$_{\text{Jup}}$ that serves as an artificial limit between planets and brown dwarfs. According to this mass-driven definition, CFBDSIR could be called an IPMO or a free-floating planet.

A major remark we can draw from these comparisons is that CFBDSIR2149’s spectrum is close to the standard BT-Settl and BSL2003 models and can be matched without using the thick clouds models that have been created to account for the peculiar spectral energy distribution of the young exoplanets orbiting HR8799 (Currie et al. 2011). Given the very high dependence of the modelised SED to the type of cloud these MBC2011 models (see the completely different SED modelised on the last row of Fig. 9 for the same gravity and temperature but with a different cloud parameter setting), the fact that one of the cloud settings matches the observed spectrum at some point of the gravity/temperature grid as well the BT-Settl or BSL2003 models do is not surprising. Burningham et al. (2011a) also
concluded that such adaptable cloud models were not necessary to account for Ross458C’s spectrum, which can be fitted with BT-Settl models which use a self-consistent cloud model over their full parameter range.

If CFBDSIR2149 is indeed a 4-7M\textsubscript{Jup} ABDMG member, this would mean that the similar cool exoplanets of late T type targeted by upcoming high contrast imaging instruments should have a spectrum closer to models prediction than the heavier/warmer HR8799 planets of early T type. This would not be surprising, since the L/T transition atmospheres are known to be much more difficult to model than late T atmospheres for field brown dwarfs. Our results suggest the same is true at low gravity, and that model predictions of the cool, low mass exoplanets to be discovered could be in fact more accurate than model predictions of the few warmer L/T transition exoplanets we already know.

6. Discussion

The ability to anchor the age and metallicity of CFBDSIR2149 through its probable membership to the AB Doradus moving group allowed us to constrain its gravity and effective temperature with atmosphere models and directly corroborate these conclusions through substellar evolution models. Comparison of the spectra to the solar metallicity atmosphere models points towards a 650-750K atmosphere with a log g of 3.75-4.1. Using stellar evolution models of [Baraffe et al. (2003)], these parameters translate into a 20 Myr to 200 Myr old, 2M\textsubscript{Jup} to 8M\textsubscript{Jup} free-floating planet. These values are therefore fully compatible with the age range and properties of the AB Doradus moving group, even though ABDMG membership strongly favours the higher mass estimate and hint, in qualitative agreement with the claim of [Burningham et al. (2011a)] that BT-Settl models underestimate the K-band flux of late T dwarfs, resulting in slightly underestimating the gravity, masses and ages of the observed T dwarfs (see Table 5). However our age and metallicity constraints do confirm that CFBDSIR2149 is a low gravity, low mass object, though not as extreme as the BT-Settl models alone would have implied. If its ABDMG membership is confirmed, this object would be a 4 to 7 M\textsubscript{Jup} T-type free-floating planet.

The fact the spectrum of this probable intermediate age free-floating planet is relatively well modelled by standard atmosphere models -with no need of ad-hoc injection of thick clouds- hints that models would be more accurate for the cool (\sim 700 K), lower mass, late-T exoplanets than for the warmer, L/T transition exoplanets such as HR8799bcede (\sim 900 – 1400 K). If CFBDSIR2149 ABDMG membership is confirmed, this would show that at temperatures cooler than the L/T transition, the overall NIR spectrum of late T objects does show low gravity features but is not dramatically different to a field late T spectrum. [Bowler et al. (2012)] and [Wahhaj et al. (2011)] studied a L0 (1RXS J235133.3+312720B) and a L4 (CD-35...

Fig. 9. Comparison of CFBDSIR2149 full spectrum at R=225 (red) with various models (black). **Upper left:** Burrows Sudarsky Lunine 2003 model for a 100 Myr, 7 M_{Jup} planet (i.e. T_{eff} ~ 750 K, log g ~ 4.1) with no clouds. **Upper right:** BT-Settl models for T_{eff}=650 K and log g =3.75. **Lower Left:** Madhusudhan et al. (2011) cloudy "E" model at T_{eff}=700 K, log g=4.0 and 60 µm enstatite particles in clouds. **Lower Right:** Madhusudhan et al. (2011) cloudy "A" model at T_{eff}=700 K, log g=4.0 and 100 µm particles in clouds.

The comparison of CFBDSIR2149 with Ross458C, has shown both are probably young planetary mass objects. Since this analysis strongly favours the young age hypothesis of Ross458C, we can expect some kind of cascade effect leading to a downward revision of the age (and therefore mass) estimates of a fraction of the late T dwarfs population. Indeed, even if CFBDSIR2149 and Ross458C are probably the youngest T dwarfs currently identified, their gravity sensitive features do not widely differ from some other known field T dwarfs. Many discovered late T dwarfs (see for instance Knapp et al. 2004; Burgasser et al. 2006; Lucas et al. 2010; Burningham et al. 2011; Liu et al. 2011) have long been classified with a low gravity (log g ≤ 4.5). Since these estimates were only grounded on the comparison of their spectra and colours to atmosphere models that have not been observationally constrained in this temperature and gravity range, the resulting planetary mass estimates have been seen as unprobable lower limits. Our results hint that many of these low-gravity late T dwarfs would actually reside below the deuterium burning mass. This supports the hypothesis that a small but significant fraction of the known population of late T dwarfs are free-floating planets, perhaps the visible counterpart of the free-floating planets population detected by microlensing by Sumi et al. (2011); Strigari et al. (2012).
The conclusions for stellar and planetary formation models would also be far reaching. Either the planetary mass-field brown dwarfs are mostly the result of a stellar formation process, which would confirm the fragmentation of a molecular cloud can routinely form objects as light as a few Jupiter masses, either these objects are mostly ejected planets. In this case, given that massive planets are less easily ejected from their original stellar system than lower mass ones, and that lighter planets are much more common than heavier ones (see [Bonfils et al. 2011] for instance), this would mean free-floating, frozen-down versions of Jupiters, Neptunes and perhaps Earths are common throughout the Milky Way interstellar ranges.

However, these speculations need the confirmation of CFBDISR2149 as a member of ABDMG moving group to become robust hypotheses. Our ongoing parallax measurement program for CFBDISR2149 will improve the proper motion measurement and determine its precise distance, which should ascertain whether or not it is an ABDMG member. It will also bring strong constraints on the absolute flux and on the radius of CFBDISR2149, enabling to use it as a well-characterised benchmark for young late T dwarfs and the T-type, Jupiter-masses exoplanets that are likely to be discovered by the upcoming SPHERE, GPI and HiCIAO instruments.
