1. Introduction

Usually one thinks of stars as stable objects, taking at least millions of years to evolve significantly. While it is true that stars take such timescales to age, they need not be “stable” in a static sense over all that time. Many stars in fact undergo pulsations on timescales between minutes and years, as for instance the Be stars Baade, Rivinius and Štěfl reported about in a recent Messenger issue (No. 107, p. 24). The most obvious pulsation mode is the radial one, where the star becomes bigger and smaller periodically, and like any expanding/compressing gas also cooler and hotter again. We see these stars varying in brightness and colour, and their spectra cyclically approaching and receding. The well known Mira in the constellation Cetus ($P = 330$ day), or the Cepheids ($P = 1…50$ day), which help in measuring extragalactic distances, are such objects. Stars may not only pulsate radially, however. Imagine a free-floating blob of water in a Space Shuttle, or a steam engine) where the role of the valve is played by a layer inside the star. The excitation process resembles a Carnot process (as in an ideal steam engine) where the role of the valve is played by a layer inside the star that turns opaque with increasing temperature due to ionization processes and becomes transparent again during such pulsations.

1. Introduction

Usually one thinks of stars as stable objects, taking at least millions of years to evolve significantly. While it is true that stars take such timescales to age, they need not be “stable” in a static sense over all that time. Many stars in fact undergo pulsations on timescales between minutes and years, as for instance the Be stars Baade, Rivinius and Štěfl reported about in a recent Messenger issue (No. 107, p. 24). The most obvious pulsation mode is the radial one, where the star becomes bigger and smaller periodically, and like any expanding/compressing gas also cooler and hotter again. We see these stars varying in brightness and colour, and their spectra cyclically approaching and receding. The well known Mira in the constellation Cetus ($P = 330$ day), or the Cepheids ($P = 1…50$ day), which help in measuring extragalactic distances, are such objects. Stars may not only pulsate radially, however. Imagine a free-floating blob of water in a Space Shuttle, or a big soap bubble. Before reaching a stable spherical shape (or popping) they undergo damped wobbles. This, in a sense, is externally excited non-radial pulsation (nrp) in a multitude of modes.

Nonradially pulsating stars behave similarly. But since these pulsations are excited from inside the star and are going on for millions of cycles, they appear more ordered as most modes are damped, and typically only one or few high-amplitude modes are excited in an nrp star. The excitation process resembles a Carnot process (as in an ideal steam engine) where the role of the valve is played by a layer inside the star that turns opaque with increasing temperature due to ionization processes and becomes transparent again during such pulsations.
the following expansion phase. When such a layer is close to the stellar surface, stellar pulsation may be excited. On the stellar surface nrp manifests itself as a global wave pattern, which travels along the stellar surface parallel to the equator and causes the periodic behaviour. This global wave pattern can be described by means of quantum numbers $\ell$ and $m$, characterizing the number of oscillation nodes along the equator and across it, similar to the two-dimensional oscillations of a drumskin (or of the VLT primary mirror, being exploited for the active optics).

Such nrp might be very subtle, as in our Sun, which pulsates in numerous low-amplitude modes with $P = 5$ min. In other stars, like the Be stars, however, the induced variability may look so violent, that it was first claimed that, if this were pulsation, the star would be disrupted. In fact, browsing the spectra of the early type Be star $\omega$ CMa after the observations taken during the Heros project (Fig. 1, see also Baade et al., op. cit.), we were convinced that the periodic variability could not be modelled without taking into account also shocks and other non-linear effects. Most notably, the variability can be observed out to higher velocities than the projected stellar rotational velocity, which would normally suggest a circumstellar origin, and the strong, narrow absorption "spikes" seemed to require severe distortions of the stellar surface (see Fig. 1 for an example). However, as will be shown, these features could be modelled without any additional assumptions with a general-purpose non-radial pulsation modelling code.

Other hypotheses proposed to explain the line profile variability ($lpv$) of Be stars, and especially of $\omega$ CMa, include starspots and co-rotating clouds. However, for none of them was a satisfying model able to reproduce the observed variations of more than a single spectral line.

Ever since the discovery of periodic $lpv$ in Be stars one has wondered whether it could be the same process that is responsible for building up the circumstellar disk. Since the mass loss modulations of early type stars are not very well understood in general, the identification of the cause of the $lpv$ in Be stars also would be a step forward in hot star physics in general.

2. A new model-code

When the Heros project started, none of the hypotheses introduced above was clearly favoured. At this point, however, a new nrp modelling code, the BRUCE/Kylie-package, was published by Rich Townsend. Several advantages made it the first choice to attempt modelling the $lpv$ of $\omega$ CMa (and other pulsating Be stars).

For instance, the pulsational surface wave pattern depends not only on $\ell$ and $m$, but also on stellar rotational velocity. With increasing rotation, the wave pattern becomes more and more concentrated towards the equator. BRUCE, other than most codes before, can compute the surface wave pattern up to the critical rotation limit. It is therefore ideally suited to Be stars, that typically rotate at about 70 to 80% of their critical speed.

Also, BRUCE is one of the few codes optimized for relatively long oscillation periods (i.e. longer than the fundamental radial oscillation mode), for which horizontal motions are the most important. These are called $g$-modes (since gravity is the most important restoring force) and are comparable to water waves in an ocean. Most other codes specialize in short period pulsation modes, where radial motions dominate, called $p$-modes (from pressure) and rather resembling sound waves.

The input parameters required by BRUCE are stellar quantities (mass, temperature, radius, rotation, and inclination), and the pulsational parameters. At first look, this seems to be a disadvantage of the code, because other codes require only the pulsational parameters, but also only compute the variability of the residuals from the mean, not the line profiles themselves. However, this is in fact a major advantage, since the variability depends strongly on properties of the spectral line modelled, which in turn are determined by the stellar parameters. The extended wavelength range of echelle data allows one to make use of the differences of individual spectral lines formed at different stellar latitudes to further constrain the model parameters. Therefore, the reproduction of the variability and the mean profile, for as many different lines as possible, not only gives the pulsational parameters, but also the stellar ones.

![Image](image_url)

Figure 2: The pulsational variations of the stellar surface as computed by BRUCE for an $\ell = 2$, $m = 2$ mode. This sectorial mode has two node-lines in longitude $\ell = 2$, thus the nrp-pattern repeats twice along the equator. The same model is shown for equator-on (upper row) and almost pole-on orientation, like $\omega$ CMa is seen from Earth (lower row, the "+" marks the rotational pole). The radial motions are a factor of almost 10 slower than the horizontal ones, while the $\varphi$- and $\theta$-amplitudes are about equal. These three velocity fields are co-added and projected onto the line of sight, before Kylie computes the observed spectrum (see also Fig. 3). The temperature changes are caused by the varying pressure.
BRUCE computes the surface parameters (such as temperature, gravity, and projected velocity) of the pulsating star for a mesh of about 25,000 points on the visible surface (Fig. 2 has been constructed from the BRUCE output). For each surface point the local spectrum is taken from an input grid of precomputed data and shifted by the projected velocity. The KYLIE program then co-adds these local spectra to the one that would be observed from Earth.

3. Reproducing spectra

How could this new code help in resolving the seemingly contradictory behaviour of ω CMa? The key is the almost polar inclination of the star. Figure 2 shows the three constituents of the pulsational velocity before projection onto the line of sight. In the equatorial view, the ϕ-velocity would dominate the visible variability at the stellar limbs. The θ-component is almost perpendicular to the line of sight, and thus suppressed by projection effects in the equatorial view. For a polar orientation of the star, the situation is reversed, however. The θ-velocity is now dominant, while the visibility of the ϕ-component is suppressed. Since the rotational velocity is also in ϕ-direction, it underlies the same projection.

The excess of 40 km s⁻¹, by which the variability is seen beyond the rotational range (such features are also called ramps), is therefore the true maximal velocity of the θ-field. Since this is 40% of the projected rotational velocity at the small inclination of ω CMa, it alters the visible line profile significantly (see Fig. 3). But it is only about 15% of the true rotational velocity, so the physical effects on the stellar surface are much less severe. This way the polar inclination amplifies the contrast of the observed variability for g-mode pulsation.

The recently published MESSENGER article by Baade et al. (op. cit.) has already presented an example of how under these conditions ramps and spikes result from the generic properties of a nonradially oscillating, rotating sphere, without the necessity to customize the model code for the specific case of ω CMa.

Figure 3 demonstrates how under these conditions ramps and spikes result from the generic properties of a nonradially oscillating, rotating sphere, without the necessity to customize the model code for the specific case of ω CMa.
Figure 5: Periodic line profile variability (lpv) of low v sin i Be stars shown in the extreme asymmetry phase. The lpv of ω CMa is the strongest, but not in principle different from other low v sin i Be stars. See also Figure 6 for a dynamical view of the lpv of FW CMa, ω CMa, and HR 4625.

Figure 6: Observed lpv of stars with different v sin i, shown as residuals from the mean line profile for two different lines. It is compared to the ω CMa model being 'viewed' at inclinations between 6º and 70º to match the indicated v sin i of the observed stars. The apparently asymmetric lpv of Mg II 4481 in 28 Cyg is caused by rotational blending with HeI 4471, visible in both observations and model data.
the resulting reproduction of the $lpv$ of HeI 4471 and MgII 4481. In Fig. 4, results for additional lines of helium and other ions are shown, all computed with the same set of stellar and pulsational parameters.

4. Do all Be stars pulsate?

Since the periodic $lpv$ of $\omega$ CMa is among the strongest known, the question needs to be addressed whether it is a typical Be star.

$\omega$ CMa is a B2 IV star. Since it is known that Be stars rotate almost critically, its low projected rotational velocity $v\sin i$ points to a pole-on orientation, which is also supported by the derived model parameters. If all (or most) other such Be stars would show this kind of periodic variability (possibly weaker, but in principle the same), the $lpv$ could be explained by $nrp$ in general.

Although most Be stars are of early B spectral type, there are not too many bright ones in the same range of $v\sin i$ as $\omega$ CMa. Searching archival data and securing additional observations with FEROS, we found most of them to show spikes like $\omega$ CMa, or a similar variability with lower amplitudes, i.e. no fully developed spikes, but global asymmetry variations, as is shown in Figure 5.

A complementary approach focuses on the observed $lpv$ of equator-on (high $v\sin i$) stars. The $lpv$ of these stars looks different from the pole-on $\omega$ CMa. But if $\omega$ CMa is proto-typical, the differences should be just inclination effects. To address this expectation the model of $\omega$ CMa was computed for a set of inclinations, so that the resulting $v\sin i$ would be the same as for some typical Be stars. Then, the modelled variations were compared to the observed ones (Fig. 6). The similarity of model and observations shows that the model of $\omega$ CMa represents a typical early-type Be star.

5. Consequences and outlook

The main result of the modelling project is the confirmation that early-type Be stars pulsate nonradially in $g$-modes. Based on the detailed modeling of $\omega$ CMa, it could be shown that this star is proto-typical, and that the periodic $lpv$ of early type Be stars in general is due to nonradial pulsation.

Several stars in the database, including $\omega$ CMa, were observed to replenish their disks via outburst events during our campaigns. Although plain $nrp$ cannot account for mass and angular momentum transfer into the disk, there is observational evidence for a connection between $nrp$ and the disk formation. Among other effects, the $lpv$ pattern of $\omega$ CMa changes in several spectral lines during an outburst, which might provide the key to understand the mass transfer mechanism between Be stars and their disks.

Just as the pulsational parameters are determined by the best fit of the variability, the stellar parameters can be determined by the best fit of the mean absolute line profile. The modeling method described above offers the potential to combine these two steps in a single analysis, due to the good reproduction of both residual variability and absolute line profile (see Fig. 6). Since nonradial pulsation breaks the symmetry of the stellar surface w.r.t. rotation, one can even derive the stellar inclination angle from the modelling, while otherwise it is inseparably factored into the projected rotational velocity $v\sin i$. Rotation is becoming increasingly important for understanding stellar structure and evolution. A method to derive $v$ and $i$ separately, utilizing the $nrp$ pattern on the stellar surface, bears great potential not only for Be stars, but for a much wider range of objects, since nonradial pulsation is widespread in the Hertzsprung-Russell-Diagram.

The VLT and the most distant quasars

L. PENTERICCI and H.W. RIX (MPIA, Heidelberg), X. FAN (IAS Princeton), M. STRAUSS (Princeton University)

1. Introduction: optical surveys for high-redshift quasars

Quasars are amongst the most luminous objects in the Universe, allowing us to study them and any intervening material out to very large distances, corresponding to look-back times when the Universe was very young. Finding and studying quasars at high redshifts is one of the best ways to constrain the physical conditions in the early Universe. The mere existence of luminous quasars at such early times, and the implication of black holes with $M \geq 10^9 M_\odot$ place stringent limits on the epoch at which massive condensed structures formed, thereby constraining structure formation models (e.g. Efstathiou and Rees 1988).

Most known high redshift quasars have been found as outliers in color space from the stellar locus in multicolor optical surveys (e.g. Warren et al. 1994, Kennefick et al. 1995). One prominent survey is the Sloan Digital Sky Survey (SDSS, York et al. 2000) which is systematically mapping one-quarter of the entire sky, producing a detailed multi-color image of it and determining the positions and absolute brightnesses of more than 100 million celestial objects. The SDSS will also measure the distance to a million of the nearest galaxies, producing a three-dimensional picture of the Universe through a volume one hundred times larger than that explored to date.

One of the principal aims of the SDSS is the construction of the largest sample of quasars ever, with more than 100,000 objects spanning a large range of redshift and luminosities, giving us an unprecedented hint at the distribution of matter to the edge of the visible Universe.

Thanks to the accurate 5 band photometry of SDSS, high redshift quasars can be efficiently selected by their distinctive position in color-color diagrams, with characteristic colors due to the main feature of the quasar spectra, viz., the strong Ly$\alpha$ emission line, the Ly$\alpha$ forest and the Lyman limit. During its first year of operation, the SDSS had already found a large number of extremely distant quasars, including more than 200 new quasars at redshift greater than 4 and the most distant quasar known, SDSS J1030 + 0524 at $z = 6.28$ (Fan et al. 2001). Until a few months ago this was also the most distant object known but it has been surpassed by a galaxy at $z = 6.56$ recently discovered by Hu et al. (2002).

2. VLT observations of the most distant quasars: testing the conditions of the early Universe

The spectra of very high redshift quasars can tell us a great deal about the conditions in the early Universe. In particular, we can use them as probes of the intergalactic medium (IGM) to determine the state of any intervening material along the line of sight.

One of the fundamental questions of modern cosmology is how and when the Universe became ionized (for a complete review see Loeb & Barkana 2001). When the Universe was very...
